1 Problem

Given x_1, x_2, \dots, x_n TB of available data for the next n days and given the amount of data a server can process s_1, s_2, \dots, s_n for n days after a fresh reboot (in TB).

Goal Choose the days on which you are going to reboot so as to maximize the total amount of data you process.

2 Dynamic Programming Algorithm

2.1 Main Idea

Breaking Problem Into Sub-problems For days 0 to n , choose to restart on day d such that $\max(f(d))$ where $f(d) = P(0, d-1) + P(d+1, n)$. Find the amount of data processed $P(i, j)$ for a range of days $[i, j]$ provided you start with a fresh server (s_1) on day i . For the right partition (days $d+1$ to n), we only need to keep track of the optimal value of data processed and the day d on which we choose to reboot. Now for the left partition (days 0 to $d-1$), repeat the same process of choosing the ideal day to reboot. This process will end when the length of the left partition, the number of days of data left to process, is 1 or 0 (when rebooting will not increase the amount of data processed).

Calculating $P(i, j)$, the Amount of Data Processed without rebooting from days i to j On each day, decide whether the amount of data the server processes is limited by the amount of available data or the processing capability of the server. Return the sum of the limiting factors (available data or power) across days i through j as $P(i, j)$.

Don't Repeat Calculations, The Essence of Dynamic Programming As we process the values of $P(i, j)$ for various $[i, j]$, we will populate a results matrix (two-dimensional array) to avoid repetitive calculations of both $P(i, j)$ and $P(a, b)$ where $i = a$ and $j = b$. This matrix will need to be of size $n+1$ rows by n columns and will be initialized with a row of zero values which represent the amount of data processed on day d if we reboot on day d .

2.2 Pseudocode

```
# X represents the sequence of x_i values indexed from 1.
# S represents the sequence of s_j values indexed from 1.
def main():
    readInput() # populate X and S lists from given input
    # P (results matrix) will be of size n+1 by n (rows by columns)
    row_init() # initialize zeroth row of P (results matrix) with 0s
    GetMaximumProcessed(X, S)

def GetMaximumProcessed(X, S):
    # Begin Populating table P
    # Days 0 to d represents the left partition.
    # Day d + 1 represents the partition day.
    # Day d + 2 to n (length of X) represents the right partition.
    for d in range(length of X):
        for j in range(length of S):
            # ensure do not waste time computing values...
            # ...that have already been computed
            # ...that are impossible to use (i.e. x_1 data processed using s_2)
            P[d][j] = Min(X[d], S[j])
            # P[d][j] depends on P[j - 1][d - 1]
            # ...because we build table P from left to right
            if P[j - 1][d - 1] is a valid cell with value 0,
                # the max of the left partition is in the d - j - 1 column
                then P[d][j] += the maximum of the d - j - 1 column.
            else if P[j - 1][d - 1] is a valid cell
                # there are columns remaining in the left portion of the table P
                then P[d][j] += P[j - 1][d - 1]
    return max value of last column in P as optimum amount of data processed
```

2.3 Traceback Algorithm

Report Path to Optimum Find the goal cell (the maximum value in the results table P) which will be in the right-most column. From the right-most column in P, get the row index of the max value in that column. Using the indices of the max value, the day that will have caused that reboot (the day on which we will partition) is the index of the column subtracted by the index of the row (e.g. *column - row*). Add the number of the day that will have caused that reboot to a set tracking the days we will reboot the server. Repeat this process for the columns on the left of the column of the last reboot (the left partition) until we do not have any more days on which to try and reboot. When there are no more days left to make a decision, we report the set of days to reboot and on all other days- we will decide to process the data.

2.4 Time Complexity

To create the results matrix (P), we must build a table of size $n + 1$ by n which takes $O(n^2)$ time: we will ignore populating some of these cell values, but this will not directly impact the asymptotic complexity of the algorithm. In addition to building the table, we will occasionally do a linear scan of a column to find its maximum value: this will take $O(n)$ time which, again, does not directly impact the asymptotic complexity of the algorithm. Other operations should take constant time, so our **algorithm runs with quadratic time complexity- $O(n^2)$** .

3 Implementation

3.1 Code

Listing 1: "Ruby Implementation"

```
1  # initialize_table will populate a 2D array (table) with an  
   initial row of 0 values  
2  def initialize_table(given, can)  
3    table = Array.new(can.length + 1)  
4      (0...(can.length + 1)).each { |x| table[x] = Array.new(given.  
      length) }  
5    (0...(given.length)).each { |x| table[0][x] = 0 }  
6    return table  
7  end  
8  
9  # output the structure of the table to the console  
10 def print_table table  
11   table.each do |x|  
12     if x != nil  
13       rowLen = x.size  
14       x.each_with_index { |y, i|  
15         if( i == (rowLen - 1) )  
16           str = "|%5d|" % y  
17           print str  
18         elsif( y == nil )  
19           print "*****"  
20         else  
21           str = "|%5d" % y  
22           print str  
23         end  
24       }  
25     end  
26     puts  
27   end
```

```

28 end
29
30 # return limiting factor (amount of data or server processing
    power)
31 def min(x, s)
32     if x < s
33         return x
34     end
35
36     return s
37 end
38
39 # return the maximum value of a specific column in a table
40 def column_max( table, column )
41     max = -9999999
42     (0...(column + 2)).each do |x|
43         if table[x][column] != nil
44             if table[x][column] > max
45                 max = table[x][column]
46             end
47         end
48     end
49
50     return max
51 end
52
53 # process the data sets X (given) and S (can)
54 def make_table( given, can )
55     table = initialize_table(given, can) # init row of 0s
56     # need one more row than columns (n + 1) rows
57     can = [0] + can
58
59     (0...(given.length)).each do |x|
60         (1...(can.length + 1)).each do |s|
61             # do not calculate min for lower diagonals
62             # cannot possibly process x_1 with the power of s_2, nor x_2
                with s_3
63             if s - x < 2
64
65                 table[s][x] = min( given[x], can[s] )
66
67                 if s == 1 && x > 1
68                     table[s][x] += column_max( table, x - s - 1 )
69                 elsif x >= 1
70                     table[s][x] += table[ s - 1 ][ x - 1 ]

```

```

71         end
72     end
73 end
74 end
75 return table
76 end
77
78 # Given a table and a column find the max in that column and
79 # return the index of that value.
80 def column_max_index( table , column )
81     max = -9999999

101     column = column - column_max_index(table , column) - 1
102
103     while column >= -1
104         reboots << (column + 1)
105
106         if column == -1
107             break
108         end
109
110         column = column - column_max_index(table , column) - 1
111     end
112     return reboots
113 end
114
115 # Our test case.

```

```

116 ourX = [10, 3, 1, 8, 6]
117 ourS = [6, 4, 3, 2, 1]
118
119 ##### MAIN #####
120
121 # Make the table
122 table = make_table( ourX, ourS )
123 # output the table
124 print_table table
125 # output DP result
126 puts "Max amount of data that could be processed : #{column_max(
127   table, table.length - 2)}"
128 # output traceback
129 print "To get this max reboot on day(s) : "
130 days = trace_back(table)
131 dayCount = days.size
132 days.each_with_index { |day, i|
133   if( i == dayCount - 1 )
134     print  "#{day+1}\n"
135   else
136     print  "#{day+1},"
137   end
138 }

```

3.2 Small Example

Given: $X = 10, 3, 1, 8, 6$ and $S = 6, 4, 3, 2, 1$
Construct the table (right) and identify the maximum cell value (19). Because the maximum value (19) is in row index 2, we know **we reboot on day number 3 only** (or the 2nd indexed day counting from 0). The program in this document produces the console output (below).

| - | 10 | 3 | 1 | 8 | 6 |
|---|----|---|----|----|-----------|
| - | 0 | 0 | 0 | 0 | 0 |
| 6 | 6 | 3 | 7 | 15 | 16 |
| 4 | - | 9 | 4 | 11 | <u>19</u> |
| 3 | - | - | 10 | 7 | 14 |
| 2 | - | - | - | 12 | 9 |
| 1 | - | - | - | - | 13 |

```

|    0|    0|    0|    0|    0|
|    6|    3|    7|   15|   16|
|*****|    9|    4|   11|   19|
|*****|*****|   10|    7|   14|
|*****|*****|*****|   12|    9|
|*****|*****|*****|*****|   13|

```

Max amount of data that could be processed: 19
To get this max reboot on day(s): 3
